

Batch optimization in VW via LBFGS

Outline

- gradient descent and Newton method
- LBFGS
- LBFGS in VW

Smooth convex unconstrained optimization

Goal: $\min_{\mathbf{w} \in \mathbb{R}^d} f(\mathbf{w})$

where f is strongly convex
and twice continuously differentiable

Our objective:

$$f(\mathbf{w}) = \sum_{i=1}^n \text{loss}(\mathbf{w}; x_i, y_i) + \frac{\lambda}{2} \|\mathbf{w}\|^2$$

- possibly weighted loss
- regularization can have coordinate-specific scaling (specified by user)

Warm-up: Gradient descent

- initialize \mathbf{w}_0
- for $t=1,2,\dots$:
move in the direction of the steepest descent
$$\mathbf{w}_{t+1} = \mathbf{w}_t - \eta \nabla f(\mathbf{w}_t)$$

Warm-up: Gradient descent

Gradient descent update:

$$\mathbf{w}_{t+1} = \mathbf{w}_t - \eta \nabla f(\mathbf{w}_t)$$

gradient

$$\mathbf{g}_t = \nabla f(\mathbf{w}_t)$$

Equivalently:

- approximate

$$f(\mathbf{w}) \approx f(\mathbf{w}_t) + \mathbf{g}_t^\top (\mathbf{w}_t - \mathbf{w}) + \frac{1}{2\eta} \|\mathbf{w}_t - \mathbf{w}\|^2$$

- optimize approximation:

$$\mathbf{w}_{t+1} = \underset{\mathbf{w}}{\operatorname{argmin}} \left(f(\mathbf{w}_t) + \mathbf{g}_t^\top (\mathbf{w}_t - \mathbf{w}) + \frac{1}{2\eta} \|\mathbf{w}_t - \mathbf{w}\|^2 \right)$$

Can we replace quadratic term by a tighter approximation?

Newton method

Hessian

$$\mathbf{H}_t = \nabla^2 f(\mathbf{w}_t)$$

Better approximation

$$f(\mathbf{w}) \approx f(\mathbf{w}_t) + \mathbf{g}_t^\top (\mathbf{w}_t - \mathbf{w}) + \frac{1}{2} (\mathbf{w}_t - \mathbf{w})^\top \mathbf{H}_t (\mathbf{w}_t - \mathbf{w})$$

Update:

$$\mathbf{w}_{t+1} = \mathbf{w}_t - \mathbf{H}_t^{-1} \mathbf{g}_t$$

Problem: Hessian can be too big (matrix of size $d \times d$)

LBFGS = a quasi-Newton method

[Nocedal 1980, Liu-Nocedal 1989]

Instead of the Newton update

$$\mathbf{w}_{t+1} = \mathbf{w}_t - \mathbf{H}_t^{-1} \mathbf{g}_t$$

Perform a *quasi-Newton* update:

$$\mathbf{w}_{t+1} = \mathbf{w}_t - \eta_t \mathbf{K}_t \mathbf{g}_t$$

where: \mathbf{K}_t is a low-rank approximation of \mathbf{H}_t^{-1}

η_t is obtained by line search

- rank m specified by user (default $m=15$)
- instead of storage d^2 , only storage $2dm$ required
(update of \mathbf{K}_t also has running time $O(dm)$ per iteration)

Line search in LBFGS

[Nocedal 1980, Liu-Nocedal 1989]

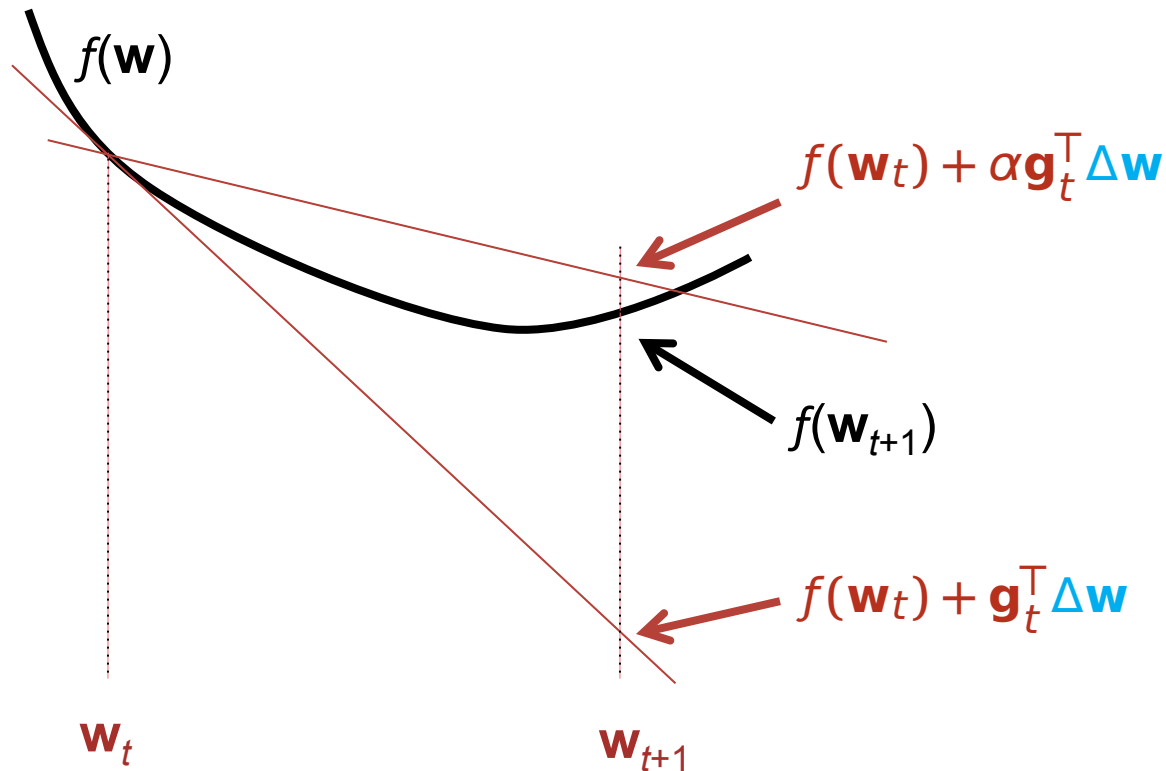

Update:

$$\mathbf{w}_{t+1} = \mathbf{w}_t - \eta_t \mathbf{K}_t \mathbf{g}_t$$

- direction determined by $\mathbf{K}_t \mathbf{g}_t$
- step size η_t must satisfy **Wolfe conditions**

1st Wolfe condition:

$$f(\mathbf{w}_{t+1}) \leq f(\mathbf{w}_t) + \alpha \mathbf{g}_t^T \Delta \mathbf{w} \quad \text{for some } \alpha \text{ in } (0, 0.5)$$

change in \mathbf{w}

$$\Delta \mathbf{w} = \mathbf{w}_{t+1} - \mathbf{w}_t$$

1st Wolfe condition:

$$f(\mathbf{w}_{t+1}) \leq f(\mathbf{w}_t) + \alpha \mathbf{g}_t^\top \Delta \mathbf{w} \quad \text{for some } \alpha \text{ in } (0, 0.5)$$

Rewrite as

$$\Delta f \leq \alpha \mathbf{g}_t^\top \Delta \mathbf{w}$$

where $\Delta f = f(\mathbf{w}_{t+1}) - f(\mathbf{w}_t)$

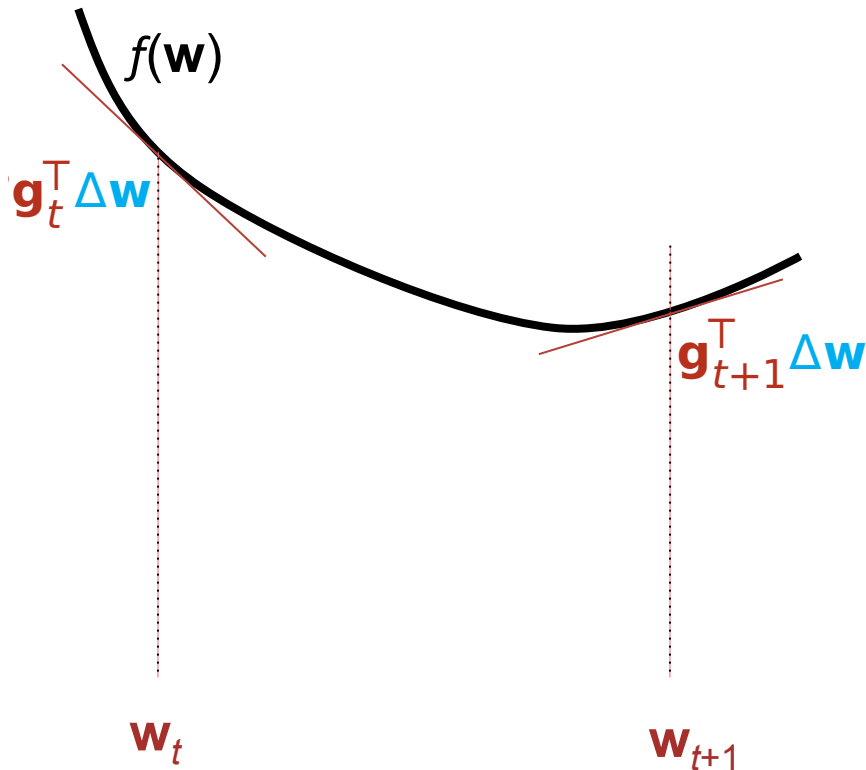

Equivalent to: $\alpha \leq \frac{\Delta f}{\mathbf{g}_t^\top \Delta \mathbf{w}}$
(because $\mathbf{g}_t^\top \Delta \mathbf{w}$ is negative)

We use notation $\text{wolfe1} = \frac{\Delta f}{\mathbf{g}_t^\top \Delta \mathbf{w}}$ for the ratio on the rhs.

2nd Wolfe condition (strengthened):

$$\left| \mathbf{g}_{t+1}^T \Delta \mathbf{w} \right| \leq \beta \mathbf{g}_t^T \Delta \mathbf{w}$$

for some β in $(\alpha, 1)$

2nd Wolfe condition (strengthened):

$$\left| \mathbf{g}_{t+1}^\top \Delta \mathbf{w} \right| \leq \beta \mathbf{g}_t^\top \Delta \mathbf{w} \quad \text{for some } \beta \text{ in } (\alpha, 1)$$

Rewrite as $\beta \geq \left| \frac{\mathbf{g}_{t+1}^\top \Delta \mathbf{w}}{\mathbf{g}_t^\top \Delta \mathbf{w}} \right|$.

We use notation $\text{wolfe2} = \frac{\mathbf{g}_{t+1}^\top \Delta \mathbf{w}}{\mathbf{g}_t^\top \Delta \mathbf{w}}$ for the ratio on the rhs.

Summarizing Wolfe conditions

$$\text{Let } \text{wolfe1} = \frac{\Delta f}{\mathbf{g}_t^\top \Delta \mathbf{w}} \text{ and } \text{wolfe2} = \frac{\mathbf{g}_{t+1}^\top \Delta \mathbf{w}}{\mathbf{g}_t^\top \Delta \mathbf{w}}.$$

Let $0 < \alpha < 0.5$, $\alpha < \beta < 1$.

- i) $\text{wolfe1} \geq \alpha$
- ii) $|\text{wolfe2}| \leq \beta$

In VW, the Wolfe conditions are not enforced

- ratios wolfe1 and wolfe2 are logged
- it is always possible to choose α and β in the hindsight as long as:
 $\text{wolfe1} > 0$ and $-1 < \text{wolfe2} < 1$

Line search and termination in VW

- in the first iteration:
 - evaluate directional 2nd derivative and initialize step size according to the one-dimensional Newton step
 - if the loss does not decrease (i.e., $\text{wolfe1} < 0$), shrink the step
- in the subsequent iterations:
 - set step size to 1.0
 - if the loss does not decrease (i.e., $\text{wolfe1} < 0$), shrink the step
- terminate if
 - either: the specified number of passes over the data is reached
 - or: the relative decrease in the objective $f(\mathbf{w})$ falls below a threshold
